How can a user effectively search?

- All the tools and techniques we have detailed so far assume that the user “knows” how to formulate her queries/preferences.
- Although with traditional DB’s and a few attributes this might be a reasonable assumption, when we consider many attributes/features it is not clear how a user might guess the right combination of weights.
  - How can one define the 64 weights for a color-based search using the weighted Euclidean distance?

Possible solutions:
- **Qualitative preferences** (e.g., Skyline): This model is likely to return too many results in high-dimensional spaces, thus one should consider, say, ranked skyline queries.
- **Browsing**: Strictly speaking, there is no search activity anymore, since the user "explores" the DB. To this end, one should devise effective methods for presenting objects and for supporting navigation.
- **User feedback**
The idea of relevance feedback

- The basic idea of relevance feedback is to shift the burden of finding the “right query formulation” from the user to the system.
- For this being possible, the user has to provide the system with some information about “how well” the system has performed in answering the original query.
- This user feedback typically takes the form of relevance judgements expressed over the answer set.
- The “feedback loop” can then be iterated multiple times, until the user gets satisfied with the answers.

Relevance judgments

- The most common way to evaluate the results is based on a 3-valued assessment:
  - Relevant: the object is relevant to the user
  - Non-relevant: the object is definitely not relevant (false drop)
  - Don’t care: the user does not say anything about the object

- Information provided by the relevant objects constitutes the so-called “positive feedback”, whereas non-relevant objects provide the so-called “negative feedback”.
  - It’s common the case of systems that only allow for positive feedback.

- “Don’t care” is needed also to avoid the user the task of assessing the relevance of all the results.
- Models that allow a finer assessment of results (e.g., relevant, very relevant, etc.) have also been developed.
A practical example (1)

Query Image

Euclidean distance 32-D HSV histograms

This is the initial query, for which 2 objects are assessed as relevant by the user

Precision = 0.3 (including the query image)

Relevance Feedback Sistemi Informativi M

A practical example (2)

Query Image

These are the results of the "refined" (new) query, generated using the 1st strategy we will see

Precision = 0.6 (including the query image)

Relevance Feedback Sistemi Informativi M
A practical example (3)

These are the results of the “refined” (new) query, generated using the 2nd strategy we will see.

Precision = 0.8 (including the query image)

A practical example (4)

And these are the results obtained by combining the 2 strategies...

Precision = 0.9 (including the query image)
Basic query refinement strategies

When the feature values are vectors, two basic strategies for obtaining a refined query from the previous one and from the user feedback are:

Query point movement:
the idea is simply to move the query point so as to get closer to relevant objects

Re-weighting:
the idea is to change the weights of the features so as to give more importance to those features that better capture, for the given query at hand, the notion of relevance

Query point movement

The 1st formulation of the query point movement (QPM) strategy dates back to 70’s, when it was proposed by J.J. Rocchio in the context of text retrieval systems based on the Vector Space model

Rocchio’s formula is:

\[ q_{\text{new}} = q_{\text{old}} + \beta \frac{\sum_{p \in \text{Rel}} (p - q_{\text{old}})}{\|\text{Rel}\|} - \gamma \frac{\sum_{p \in \text{NonRel}} (p - q_{\text{old}})}{\|\text{NonRel}\|} \]

where:
- \( q_{\text{old}} \) is the previous query point
- \( \text{Rel} \) is the set of relevant objects that have been retrieved by \( q_{\text{old}} \)
- \( \text{NonRel} \) is the set of non-relevant objects that have been retrieved by \( q_{\text{old}} \)
- \( \beta \) and \( \gamma \) are non-negative parameters that control at which speed the query point moves towards relevant objects and far from non-relevant objects
QPM: geometric view

- Basically, Rocchio’s formula adds to the (scaled) old query point the (scaled) centroid, \( g \), of relevant (“good”) objects, and subtracts the (scaled) centroid, \( b \), of non-relevant (“bad”) objects:

\[
q_{\text{new}} = q_{\text{old}} + \beta \times (g - q_{\text{old}}) - \gamma \times (b - q_{\text{old}})
\]

\[
= (1 - \beta + \gamma) q_{\text{old}} + \beta \times g - \gamma \times b
\]

QPM: some observations

- Let \( \gamma = 0 \) and \( \beta = 1 \). Then \( q_{\text{new}} = g \), thus the new query point coincides with the center of relevant objects.
- This strategy (which is the 1st one used in the image retrieval example) can sometimes lead to “overshoot” the region of relevant objects.

- Overshooting can also occur with large values of \( \gamma \). Indeed, it’s easy to construct examples where negative feedback will move the query point towards non-relevant objects.
  - This is a reason why negative feedback is rarely used, even if some recent proposals [AGG02] present more robust solutions.

Relevance Feedback Sistemi Informativi M
The idea of the re-weighting strategy is to analyze the relevant objects in order to understand if some feature (dimension) is more important than others in determining “what makes an object relevant.”

For the relevant case of weighted Euclidean distances, the re-weighting strategy is easily implemented as follows:

- Let $\text{Rel} = \{p_1, \ldots, p_{|\text{Rel}|}\}$ be the set of relevant objects retrieved by $q_{\text{old}}$.
- Let $p_{i,j}$ be the feature value of $p_j$ for the $i$-th feature ($i=1,\ldots,D$).

The weight $w_i$ of the $i$-th feature is estimated as $w_i \propto 1/\sigma_i^2$, that is, the inverse of the variance of feature values along the $i$-th coordinate.

Besides the intuition, this strategy has a theoretical justification, which relies on the minimization of distances from the relevant objects [RH00].
Other approaches

- Several other approaches to implement relevance feedback strategies exist
- In particular:

  MindReader [ISF98] solves the problem by looking for the optimal ellipsoid that minimizes the sum of distances from relevant objects.

Query expansion techniques replace the original query point with multiple query points.

However, when |Rel| < D, the corresponding linear optimization problem is unconstrained, and the approach is not applicable.

User feedback: other scenarios

- Relevance feedback is the basic mechanism to implement an effective user-system interaction.

- User feedback also arises in other contexts:
  
  - If the systems keeps trace of user feedback through time, this will lead to the formation of "user profiles", which can subsequently be exploited for selectively disseminating new information (information filtering).
  
  - If what is returned to a given user exploits the feedback ("opinions") expressed by other users, we move towards the areas of collaborative filtering and recommender systems.
